Cavity-optomechanical systems realized in single-crystal diamond are poised to benefit from its extraordinary material properties, including low mechanical dissipation and a wide optical transparency window. Diamond is also rich in optically active defects, such as the nitrogen-vacancy (NV) and silicon-vacancy (SiV) centers, which behave as atom-like systems in the solid state. Predictions and observations of coherent coupling of the NV electronic spin to phonons via lattice strain have motivated the development of diamond nanomechanical devices aimed at the realization of hybrid quantum systems in which phonons provide an interface with diamond spins. In this work, we demonstrate diamond optomechanical crystals (OMCs), a device platform to enable such applications, wherein the co-localization of ~200 THz photons and few to 10 GHz phonons in a quasi-periodic diamond nanostructure leads to coupling of an optical cavity field to a mechanical mode via radiation pressure. In contrast to other material systems, diamond OMCs operating in the resolved-sideband regime possess large intracavity photon capacities (>10⁵) and sufficient optomechanical coupling rates to reach a cooperativity of ~20 at room temperature, allowing for the observation of optomechanically induced transparency and the realization of large-amplitude optomechanical self-oscillations.

1. INTRODUCTION

Optomechanical crystals (OMCs), first demonstrated in silicon [1] and later in other materials such as silicon nitride [2,3], aluminum nitride [4,5], and gallium arsenide [6,7], have emerged as a fruitful optomechanics platform, wherein radiation pressure effects provide exquisitely sensitive optical control of mechanical vibrations. Such systems have enabled demonstrations of quantum ground-state cooling [8], optomechanically induced transparency (OMIT) [9], squeezed light [10], and wavelength conversion [11]. Highly coherent photon–phonon interactions in OMCs are a direct result of the ability to engineer a large single-photon optomechanical coupling rate (κγ) while retaining sufficiently small optical (κ) and intrinsic mechanical (γ) dissipation rates. Similar structures realized in single-crystal diamond, which features a unique combination of superior mechanical, thermal, and optical properties [12], are expected to exhibit pronounced optomechanical interactions, quantified by the cooperativity parameter $C = 4n_0\gamma_p^2/\kappa\gamma_i$ (where $n_0$ is the intracavity photon number). Specifically, the wide bandgap of diamond (~5.5 eV) precludes multi-photon absorption over a wide wavelength range (from visible to infrared). This, combined with their high thermal conductivity and small thermal expansion, enables monolithic diamond optical cavities that can withstand significant optical power densities, while avoiding degradation in optical linewidth or drifts in resonance wavelength due to thermal lensing. The large intracavity photon capacity of diamond can thus result in the high cooperativities necessary for either strong mechanical driving or effective laser cooling [8]. Moreover, diamond is among the stiffest materials known and possesses extremely low thermo-elastic mechanical damping, with recently demonstrated monolithic diamond cantilevers exhibiting mechanical Q-factors in excess of $10^6$ at room temperature [13]. In what follows, we make use of these features to demonstrate OMCs in single-crystal diamond with unique performance. Our diamond OMCs support an optical mode at $\omega_o/2\pi \sim 200$ THz, co-resonant with two localized acoustic phonon modes at $\omega_{ph}/2\pi \sim 5.5$ and ~9.5 GHz. Both mechanical resonances are well coupled to the optical cavity, with vacuum optomechanical coupling rates of.
g_o/2π ~ 120 and ~220 kHz, respectively. With a measured optical linewidth of κ/2π ~ 1.1 GHz, our diamond OMC system operates in the so-called resolved sideband regime (ω_o/κ ≫ 1), necessary for efficient radiation-pressure-driven dynamic backaction. This enables our diamond OMCs to be optically driven to C ≫ 1 at room temperature, highlighted by the observations of “phonon lasing” [14] and OMIT [9] in our structures.

2. DIAMOND OPTOMECHANICAL CRYSTAL DESIGN AND FABRICATION

The OMCs of this work consist of a one-dimensional nanobeam photonic crystal cavity fabricated in synthetic single-crystal diamond [15] using previously developed “angled-etching” techniques [16,17]. The nanobeam cavity is based on a diamond waveguide with a triangular cross-section that is perforated with a periodic lattice of elliptically shaped air holes. One unit cell of the waveguide and corresponding photonic band structure are shown in Figs. 1(a) and 1(b), respectively. The latter includes both transverse electric (TE-like, solid black lines) and transverse magnetic (TM-like, dashed blue lines) guided modes, while the gray shaded region indicates the continuum of radiation and leaky modes that exist above the light line for the structure. In this work, we focus on TE-like modes [see Fig. 1(b) inset] near the X-point frequency of ω_o/2π ~ 200 THz (λ ∼ 1550 nm), since they can lead to the realization of very high Q-factor optical cavities [15]. Importantly, our photonic crystal waveguide also supports acoustic guided modes that spatially overlap with optical modes and can couple to them via radiation pressure. The corresponding mechanical band structure [Fig. 1(c)] reveals a rich library of guided acoustic modes in the few to ~12 GHz frequency range (see Supplement 1 for extended discussions [18]). The guided modes, categorized by even (solid black lines) and odd (dashed blue lines) vector symmetries about the xz-plane, yield symmetry-based quasi-bandgaps. Following OMC design rules [19,20], we identified the guided modes derived from the Γ-point of the fourth and seventh y-symmetric bands (frequencies of ω_o/2π ~ 6.9 and ∼11.5 GHz), referred to hereafter as the “flapping” and “swelling” acoustic guided modes [Figs. 1(d) and 1(e), respectively, as the mechanical modes of interest for large optomechanical coupling. To produce an optimized diamond OMC design, we focus on the acoustic flapping mode due to the large quasi-bandgap below its native band, which is indicated by the shaded pink region in Fig. 1(c).

To realize a diamond OMC cavity from the aforementioned OMC waveguide, the lattice of air holes is chirped [19] so as to transition from a “mirror” region formed by the base unit cell in Fig. 1(a) to a “defect” cell. The selected defect cell dimensions simultaneously raise and lower the frequencies of the target optical and mechanical modes, respectively, into their corresponding quasi-bandgaps. Gradually reducing the unit cell lattice constant while also decreasing the air hole aspect ratio (h_f/h_s) achieves the necessary band-edge tuning [see the right and left panels of Figs. 1(b) and 1(c), respectively]. An optimized design [18] was determined via numerical optimization methods based on FEM simulations (COMSOL) to calculate the optical (ω_o) and mechanical (ω_m) cavity resonance frequencies, the optical Q-factor (Q_o), and g_o. Both the moving boundary (g_o,MB) and photoelastic (g_o,PE) contributions to the single-photon optomechanical coupling rate were considered [18], with the calculation of g_o,PE performed using the following photoelastic coefficients of diamond [21]: (p_{11}, p_{12}, p_{44}) = (−0.25, 0.043, −0.172). The normalized electric field (E_z) and mechanical displacement profiles (xy plane) of the final optimized diamond OMC design are shown in Figs. 1(f) and 1(g), respectively. The optimized design,
The final coupling rate for this design was \( \omega / 2\pi = 196 \text{ THz} \) \((\lambda_o = 1529 \text{ nm})\), a radiation-limited optical \( Q \)-factor of \( 7.4 \times 10^5 \), a mode volume of \( 0.57(\lambda/\pi)^3 \), an acoustic flapping mode mechanical resonance at \( \omega_m / 2\pi = 6.18 \text{ GHz} \), and zero-point motion of \( x_{zpf} = 3.1 \text{ fm} \). The final coupling rate for this design was \( g_o / 2\pi = 136 \text{ kHz} \) and included a moving boundary and photoelastic contribution of \( g_{\text{AMB}} / 2\pi = 62 \text{ kHz} \) and \( g_{\text{PE}} / 2\pi = 74 \text{ kHz} \), respectively.

With our final diamond OMC design optimized for the acoustic flapping mode, we also observe a localization of the previously mentioned acoustic swelling mode [displacement profile shown in Fig. 1(b)] at a mechanical frequency of \( \omega_m / 2\pi = 9.01 \text{ GHz} \), with a zero-point motion of \( x_{zpf} = 2.2 \text{ fm} \). The simulated optomechanical coupling rate for this design was \( g_o / 2\pi = 234 \text{ kHz} \), which includes a moving boundary and photoelastic contribution of \( g_{\text{AMB}} / 2\pi = 50 \text{ kHz} \) and \( g_{\text{PE}} / 2\pi = 184 \text{ kHz} \), respectively. We attribute the overall greater optomechanical coupling rate of the acoustic swelling mode to its cross-sectional strain profile, which more favorably overlaps with the TE-like optical mode. While this mode is better coupled to the localized optical cavity, its predicted mechanical resonance frequency is not fully isolated within a symmetry-based quasi-bandgap [see Fig. 1(c)], which may ultimately limit its mechanical \( Q \)-factor in fabricated structures [1,20].

As previously mentioned, the fabrication of the diamond OMCs utilized angled-etching techniques [15–18] [as illustrated in Fig. 2(a)], which employ anisotropic oxygen-based plasma etching at an oblique angle to the substrate surface, resulting in suspended structures with a triangular cross-section. The final fabricated structures, displayed in Figs. 2(b)–2(d), reveal excellent reproductions of the intended design. A unique feature of angled-etched structures is their triangular cross-sectional symmetry [18]. The high-resolution SEM image shown in Fig. 2(c) reveals a fabricated diamond OMC (oriented upside down), with the insets displaying a tilted cross-sectional view.

### 3. OPTICAL AND MECHANICAL SPECTROSCOPY

The fiber-optical characterization setup [18] used to perform both optical and mechanical spectroscopy of diamond OMCs is schematically displayed in Fig. 3(a). Briefly, light from a tunable laser source (TLS) was evanescently coupled to the device under test via a dimpled fiber taper. A small portion of laser signal fed to a wave meter enabled continuous monitoring of the laser frequency. An erbium-doped fiber amplifier (EDFA) was used in certain experiments to increase the maximum input laser power, and a variable optical attenuator (VOA) was used to set the final laser power delivered to the device. The optical cavity transmission spectrum was collected by a low-speed (125 MHz) photodetector, while a high-speed (12 GHz) photoreceiver monitored the RF response of the mechanical cavity via a real-time spectrum analyzer (RSA). For the OMIT measurements discussed later in this work, an electro-optic phase modulator (EOPM), placed in the input fiber path, was used to create a weak tunable probe signal on the pump-laser control field. Port 1 of a high-frequency vector network analyzer (VNA) supplied the RF input to the EOPM, while port 2 of the VNA collected the RF output of the high-speed photoreceiver. All measurements were performed at room temperature and ambient pressure.

A transmission spectrum of a representative diamond OMC, displayed in Fig. 3(b), reveals the optical cavity resonance centered at \( \lambda_o = 1529.2 \text{ nm} \), with a measured total and intrinsic optical \( Q \)-factor of \( Q_t \sim 1.76 \times 10^5 \) and \( Q_i \sim 2.70 \times 10^5 \), respectively. The corresponding total cavity decay rate, fiber taper coupling rate, and intrinsic optical decay rate are \( \kappa / 2\pi = 1.114 \text{ GHz} \), \( \kappa_f / 2\pi = 399 \text{ MHz} \), and \( \kappa_i / 2\pi = 715 \text{ MHz} \), respectively. With the input laser slightly detuned from the optical cavity, the broadband RF spectrum of thermally excited motion at room temperature [i.e., thermal Brownian motion] reveals a series of mechanical resonances [18], as shown in the normalized power spectral density (PSD) in Fig. 3(c). Specifically, we attribute the sharp resonance observed at \( \sim 5.5 \text{ GHz} \) to the diamond OMC acoustic flapping mode. A high-resolution RF spectrum [shown

Fig. 3. Diamond optomechanical crystal optical and mechanical mode spectroscopy. (a) Schematic of the fiber-optical characterization setup (see Supplement 1 for description of symbols). The inset is an optical micrograph of the dimpled fiber taper in contact with the diamond OMC under test. (b) Normalized optical transmission spectrum, centered at $\lambda_c = 1529.2$ nm ($\omega_c/2\pi = 196$ THz), of a representative diamond OMC. A Lorentzian fit (solid red curve) yields a measured optical $Q$-factor of $1.76 \times 10^5$, corresponding to an optical linewidth of $\kappa \sim 1.11$ GHz. (c) Normalized power spectral density (PSD) revealing the broadband radio frequency spectrum of optically transduced diamond OMC thermal Brownian motion (at room temperature). Sharp resonances are attributed to various localized and extended acoustic phonon modes of the diamond OMC [18]. (d) High-resolution PSD of the diamond OMC acoustic “flapping” mode centered at $\omega_m/2\pi = 5.52$ GHz. The Lorentzian fit (solid red curve) estimates a mechanical $Q$-factor of $\sim 4100$. (e) PSDs of the acoustic flapping mode and optical transmission (white circles) plotted versus input laser wavelength, indicating significant optomechanical transduction occurs with the laser detuned approximately $\pm 45$ pm from the optical cavity resonance. A clear optical bistability is present in the optical cavity transmission spectrum. The (f) optically amplified mechanical loss rate and (g) optical spring-shifted mechanical frequency (gray circles) measured as a function of laser detuning at a constant intercavity photon number of $n_i = 10,000$. The optical transmission spectrum (blue circles) is also plotted, with vertical gray dashed lines indicating $\Delta = \pm \delta\omega_m$. Fits to (f) and (g) yield estimates of $\gamma/m = 1.37$ MHz and $g_e/m = 118$ kHz.

in Fig. 3(d)] of this feature reveals a Lorentzian mechanical resonance of the diamond OMC centered at $\omega_m/2\pi = 5.52$ GHz with a room temperature mechanical $Q$-factor of $Q_m \sim 4100$.

Given the measured optical cavity decay rate, our diamond OMC operates in the resolved sideband regime with $\omega_m/\kappa \sim 4.86$. In this regime, while the input laser is either red- or blue-detuned from the optical cavity by a mechanical frequency ($\Delta = (\omega_r - \omega_l) = \pm \omega_m$), the mechanical motion of the acoustic mode phase modulates the transmitted light, giving rise to a sideband of the input laser resonant with the optical cavity. The other first-order motional sideband, which is not resonant with the optical cavity, is suppressed in this scenario. As a result, the mechanical motion produces an intensity modulation in the RF power spectrum of the photoreceiver signal. To observe this effect directly, a weak input laser was tuned across the optical cavity at a constant power, while simultaneously monitoring the RF spectrum near the diamond OMC acoustic flapping mode. Figure 3(e) displays the collected spectra as a function of laser detuning, with the simultaneously collected optical transmission spectrum also plotted. A clear increase in optomechanical transduction is observed as the laser is tuned off-resonance from the optical cavity by $\pm 45$ pm, corresponding to a detuning of approximately a mechanical frequency. Additionally, strong transduction occurs with the laser tuned within the cavity bandwidth, and a clear optical bistability is present in the optical cavity transmission spectrum. We attribute both observations to optical absorption (likely due to surface contamination), which causes a thermo-optic red shift in the optical resonance wavelength and an increase in the thermal Brownian motion of the mechanical cavity. To mitigate such thermal effects, a similar measurement was performed, but now with the input laser power continually adjusted via the VOA to maintain a constant intracavity photon number at each laser detuning [Figs. 3(f) and 3(g)]. From the measured optical cavity resonance frequency and linewidth, $n_i$ is calculated by the relation

$$n_i = P_i \frac{\kappa/2}{\hbar \omega_i (\kappa/2)^2 + \Delta^2},$$

where $P_i$ is the input laser power set by the VOA. In the resolved sideband limit [22], optomechanical backaction causes additional mechanical damping ($\gamma_{OM}$) and springing ($\delta \omega_m = |\omega_m - \omega_{m0}|$) rates, respectively, of
\[
\gamma_{\text{OM}} = 2n_c |g_c|^2 \frac{1}{i(\Delta - \omega_m) + \kappa/2} - \frac{1}{i(\Delta + \omega_m) + \kappa/2},
\]

(2)

and

\[
\delta \omega_m = n_c |g_c|^2 \frac{1}{\sqrt{i(\Delta - \omega_m) + \kappa/2}} - \frac{1}{i(\Delta + \omega_m) + \kappa/2}.
\]

(3)

Under optimal detuning, with \(\Delta = \pm \omega_m\), a maximum optomechanically induced damping rate of \(\gamma_{\text{OM}} = \pm 4n_c g_c^2/\kappa\) is expected. Figures 3(f) and 3(g) display the experimentally derived damping and springing curves (gray circles) for the diamond OMC acoustic flapping mode, respectively. A weak intra-cavity power, corresponding to \(n_c \sim 10,000\) photons, was used for this measurement to avoid any thermal drifts in the cavity resonance. Indeed, the optomechanically induced damping is maximized (minimized) when the laser is detuned a mechanical frequency \(\Delta\) away from the mean value extracted from the \(\gamma_{\text{OM}}\) red and \(\gamma_{\text{blue}}\) data points, yielding an \(\sim 1.41 \pm 0.06\) MHz. The inset of Fig. 4(a) displays the optomechanically induced damping \(\gamma_{\text{OM}} = \gamma_{\text{red}} - \gamma_{\text{blue}}, \) black squares) plotted versus \(n_c\). A linear fit to the \(\gamma_{\text{OM}}\) data yields \(\gamma_{\text{blue}} = 2\pi \Delta \approx 123 \pm 6\) kHz, which agrees well with the simulations and is consistent with previous estimates from the data plotted in Figs. 3(f) and 3(g). With the laser blue-detuned by a mechanical frequency, the threshold where \(\gamma_{\text{blue}} \approx 0\) is reached at approximately \(n_c, \text{thr} \sim 27,000\), exciting the diamond OMC mechanical cavity into large amplitude optomechanical self-oscillations, so-called "phonon lasing" [14]. Mechanical spectra of the diamond OMC taken below, at, and above this phonon-lasing threshold [shown in Fig. 4(b)] show an over 70 dB increase in the peak mechanical amplitude [Fig. 4(b) inset].

The optomechanical cooperativity \(C \equiv \gamma_{\text{OM}}/\gamma_{\text{thr}}\) is plotted versus \(n_c\) in Fig. 4(c). To drive \(\gamma_{\text{OM}}\) beyond the level reached with the tunable laser output alone (i.e. to enable larger \(n_c\)), an EDFA was inserted before the VOA to increase the maximum input laser power. With the laser red-detuned by a mechanical frequency, a maximum cooperativity of \(C \sim 6.6\) was reached for the acoustic flapping mode, as represented by the open squares in Fig. 4(b).

**Fig. 4.** Acoustic flapping mode "phonon lasing" and optomechanically induced transparency. (a) Measured mechanical linewidths \(\gamma\) collected at laser detuning of \(\Delta = +\omega_m\) (\(\gamma_{\text{red}}, \) red circles) and \(\Delta = -\omega_m\) (\(\gamma_{\text{blue}}, \) blue circles), up to the maximum laser power (corresponding to intracavity photon number of \(n_c \sim 63,000\)). Gray circles, which indicate the intrinsic mechanical linewidth values \(\gamma_{\text{thr}}\) obtained by taking the average of the detuned data, yield an estimate of \(\gamma_{\text{thr}} = 2\pi \Delta \approx 1.41 \pm 0.06\) MHz. The inset displays calculated optomechanically induced damping \(\gamma_{\text{OM}} = \gamma_{\text{red}} - \gamma_{\text{blue}}, \) gray squares), plotted versus \(n_c\). A linear fit (red solid line) yields a coupling rate of \(g_c/2\pi \approx 123 \pm 6\) kHz. Under blue laser detuning, a threshold input power of \(n_c, \text{thr} \sim 27,000\) (vertical blue dashed line) is required to observe phonon lasing of the mechanical cavity. (b) Normalized power spectral densities collected below, at, and above the phonon lasing threshold input power. The inset plots the peak PSD amplitude versus \(n_c\) with a \(\sim 72\) dB increase observed above threshold. (c) Cooperativity values \(C \equiv \gamma_{\text{OM}}/\gamma_{\text{thr}}\) collected under red laser detuning, plotted versus \(n_c\). Solid gray squares and the linear fit (solid red line) are calculated from the \(\gamma_{\text{OM}}\) values shown in the panel (a) inset. Open gray squares correspond to mechanical spectra collected with the input laser amplified by an erbium doped fiber amplifier. The extrapolated linear fit (dashed green line) was used to infer the corresponding \(n_c\) values. (d) Normalized broadband OMIT spectra \(|S_{21}|/\max(|S_{21}|)\) collected with the control laser \((\omega_c)\) red detuned approximately \(\Delta_c \equiv (\omega_c - \omega_m) \sim (\omega_m + 580\) MHz, \(\omega_m + 490\) MHz), plotted versus probe laser \((\omega_l)\) detuning \(\Delta_l \equiv (\omega_l - \omega_m)\). Right inset panels of (d) display zoomed-in OMIT spectra of the transparency window induced by coherent interaction of the mechanical and optical cavities. Fits to OMIT spectra [18] (solid red and blue lines) estimate a cooperativity of \(C \sim 1.9\) for data collected with \(\Delta_m \sim \omega_m\).
Amplified spontaneous emission (ASE) optical noise output by the EDFA prevented a direct estimate of the intracavity photon number. However, from previous estimates of $k$, $\gamma_1$, and $g_r$, a maximum intracavity photon number of $n_{c,max} \sim 159,000$ was inferred (as indicated by the extrapolated dashed linear fit). Beyond this input power level, thermo-optic bistability shifts made it difficult to achieve precise laser detuning equal to a mechanical frequency. In relation to previously reported limits, diamond OMCs have an intracavity photon capacity nearly twice as large as OMC structures realized in silicon nitride [2,3].

With the demonstration of $C \gg 1$, optomechanical transduction in our diamond OMC acoustic flapping mode occurs at a substantially faster rate than energy loss of the system. This enables observations of the optomechanical analog to electromagnetically induced transparency, the so-called OMIT [9]. To observe OMIT in our diamond OMC structures, the input laser is red-detuned from the optical cavity and fixed as a strong driving control field $(\omega_r)$, while a weak probe field $(\omega_p)$, realized as sidebands created by an EOPM, is swept in frequency across the optical cavity resonance. Under optimal detuning conditions, whereby the control laser detuning equals a mechanical frequency $(\Delta_w \equiv (\omega_r - \omega_w))$ and the probe-control detuning satisfies a two-photon resonance condition $(\Delta_p \equiv (\omega_p - \omega_w) = \Delta_p)$, destructive interference of probe photons with control photons scattered by the mechanical resonator occurs. This yields a transparency window on the optical cavity transmission spectra, with its bandwidth set by the mechanical damping rate. A central requirement for this scattering phenomenon is that the probe and phonon-scattered photons are phase coherent, which demonstrates a coherent interaction of the resonator cavity with the optical cavity. As previously mentioned, OMIT in our diamond OMC structures is observed via an $|S_{21}|$ measurement with a VNA [Fig. 3(a)], where port 1 of the VNA drives the EOPM input to create the weak probe field, which sweeps across the optical cavity, and port 2 collects the RF output of the high-speed photoreceiver. Figure 4(d) displays a representative series of normalized OMIT spectra $(|S_{21}|/\max{|S_{21}|})$ collected with the control laser detuned approximately $\Delta_w \sim (490$ MHz, $\omega_w (\omega_r + 580$ MHz)), and an intracavity photon number of $n_c \sim 59,000$. In these broadband OMIT spectra, we observe a clear dip representing the transparency window [right inset panels of Fig. 4(d)] display zoomed-in spectra of this fine feature. Fits to the normalized OMIT spectra [18], which followed the methodology reported previously [2,3], estimate a cooperativity of $C \sim 1.9$ for data collected with optimal $\Delta_w \sim \omega_m$ detuning, in good agreement with the cooperativity value measured in Fig. 4(c) under a similar input laser power.

In addition to the resonance feature at $\sim 5.5$ GHz, two sharp features are also observed in the diamond OMC broadband thermal Brownian motion RF spectrum [Fig. 3(c)] near $\sim 9.5$ GHz. Figure 5(a) displays a zoomed-in RF spectrum around these features, collected with a weak laser signal slightly detuned from the optical cavity resonance. Four clear resonances are present in this span, with the central feature at $\sim 9.5$ GHz most strongly transduced by the optical cavity field. A high-resolution RF spectrum [shown in Fig. 5(b)] of this feature reveals a Lorentzian mechanical resonance of the diamond OMC centered at $\omega_m/2\pi = 9.45$ GHz with a mechanical $Q$-factor of $Q_m \sim 7700$. This corresponds to an $f \cdot Q$ product of $7.3 \times 10^{13}$ Hz, which is among the highest demonstrated for either bulk or small-scale single-crystal diamond mechanical oscillators at room temperature [23,24].

As before, we extract the optomechanical coupling rate for this mode by tuning the laser across the optical cavity resonance while maintaining a constant intracavity photon number of $n_c \sim 6000$ and simultaneously monitoring the mechanical resonance at $9.45$ GHz. Fitting Eqs. (2) and (3) to the collected mechanical linewidth and frequency data [displayed in Figs. 5(c) and 5(d), respectively] yields an estimate for the intrinsic mechanical damping of $\gamma_r/2\pi \sim 1.18$ MHz and the single-photon optomechanical coupling rate of $g_r/2\pi \sim 239$ kHz. This value, as well as that of the mechanical resonance frequency, is in good agreement with

![Figure 5](image-url)
the simulation results obtained for the diamond OMC acoustic swelling mode shown in Fig. 1(c). Repeating similar measurements on the other ∼9.5 GHz resonances observed in Fig. 5(a) confirmed the mechanical mode at \( \omega_m/2\pi = 9.45 \) GHz couples most strongly to the optical cavity. We believe that these additional resonances are likely of similar modal character, but hybridized with guided body modes of the diamond OMC, given the lack of isolation in an acoustic quasi-bandgap [25].

Figure 5(e) plots the measured mechanical linewidth of the diamond OMC acoustic swelling mode, collected under optimal red- and blue-sideband laser detuning (\( \Delta = \pm \omega_m \)) as a function of the input power, up to the maximum output of the laser, as well as with the amplified laser pump. In this instance, with the increased sideband resolution of \( \omega_m/\kappa \sim 8.5 \), the maximum laser power output corresponds to only \( n_i \sim 29,000 \) photons. The mean value extracted from the \( \gamma_{\text{red}} \) and \( \gamma_{\text{blue}} \), data points yields an estimated intrinsic mechanical linewidth of \( \gamma/2\pi \sim 1.27 \pm 0.02 \) MHz. A plot of the optomechanical cooperativity versus \( n_i \), shown in Fig. 5(b), yields a second estimate for the optomechanical coupling rate of \( g_c/2\pi \sim 217 \pm 12 \) kHz, which is consistent with previous estimates for the diamond OMC acoustic swelling mode. From Fig. 5(f), the threshold power for the observation of optomechanical self-oscillations [18] under optimal blue-detuning was only \( n_{\text{thr}} \sim 7600 \). Under optimal red-detuned laser conditions, the increased laser power afforded by the input EDFA enabled us to reach a room temperature mechanical linewidth \( \gamma_{\text{red}}/2\pi \sim 26.7 \) MHz, which corresponds to a maximum observed cooperativity of \( C \sim 19.9 \) [Fig. 5(f)]. With previous estimates of \( \kappa, \gamma, \) and \( g_c \) for this acoustic swelling mode, an intracavity photon number of \( n_i \sim 162,000 \) was inferred at this cooperativity level. Thus, the much larger maximum cooperativity value measured for this acoustic swelling mode relative to the flapping mode is primarily the result of the increased optomechanical coupling rate. As before, higher cooperativities were not observed due to instabilities in the measurement under the high optical input power. OMIT was also observed for this acoustic swelling mode [18].

4. CONCLUSIONS

In summary, we have demonstrated resolved sideband cavity-optomechanics in a single-crystal diamond operating in the few to ∼10 GHz range, where optomechanical coupling via radiation pressure was sufficient to reach a room temperature cooperativity of nearly ∼20 for an intracavity photon population on the order of 10^5. Present devices also offer a promising platform for reaching much larger cooperativities when, for instance, operated at cryogenic temperatures, where mechanical Q-factors of diamond resonators have been shown to improve significantly [13]. Moreover, incorporating diamond color centers with monolithic OMCs is an interesting route to applications in quantum-nonlinearity optomechanics. Diamonds are rich in optically active defects (color centers), such as the nitrogen-vacancy (NV) and silicon-vacancy (SiV) center, which behave as atom-like systems in the solid state [26,27]. Recent experiments [23,28–34] exploring coherent coupling of the NV electronic spin to phonons in mechanical resonators via lattice strain have demonstrated manipulation of the NV spin state at large driven mechanical amplitudes but remain far below the strong spin-phonon coupling regime. One way to boost this interaction would be to engineer truly nanoscale resonators, with feature sizes of a few hundred nanometers, and with frequencies in the hundreds of MHz to few GHz range. Such mechanical modes would provide a large change in the local strain per phonon [31]. The localized phononic modes of OMCs not only satisfy these requirements [35], with critical dimensions (i.e., the width of dielectric bridges between subsequent air holes) already in the order of ∼200 nm, but also are conveniently actuated and transduced with optical fields in the well-established telecom wavelength range. Diamond OMCs with coupled color centers may ultimately be used to map nonclassical spin qubit states as well as quantum states of light onto phonons and vice versa [36], and they will enable fundamentally new ways to prepare, control, and read out the quantum states of diamond spin qubits. Lastly, individual diamond OMCs integrated into larger arrays coupled through phononic waveguides [25] could enable long-range spin-spin interactions mediated by phonons [37].

We note that, parallel to this work, Mitchell et al. have demonstrated cavity optomechanics in single-crystal diamond microdisks [38].
